SUMMARY

Although uridine-rich small nuclear RNAs (U-snRNAs) are essential for pre-mRNA splicing, little is known regarding their function in the regulation of alternative splicing or of the biological consequences of their dysfunction in mammals. Here, we demonstrate that mutation of \( \text{Rnu2-8} \), one of the mouse multicopy U2 snRNA genes, causes ataxia and neurodegeneration. Coincident with the observed pathology, the level of mutant U2 RNAs was highest in the cerebellum and increased after granule neuron maturation. Furthermore, neuron loss was strongly dependent on the dosage of mutant and wild-type snRNA genes. Comprehensive transcriptome analysis identified a group of alternative splicing events, including the splicing of small introns, which were disrupted in the mutant cerebellum. Our results suggest that the expression of mammalian U2 snRNA genes, previously presumed to be ubiquitous, is spatially and temporally regulated, and dysfunction of a single U2 snRNA causes neuron degeneration through distortion of pre-mRNA splicing.

INTRODUCTION

Splicing of pre-mRNAs is performed by the spliceosome machinery consisting of numerous proteins and five small nuclear RNAs (snRNAs) (Wahl et al., 2009). Assembly of the major spliceosome, responsible for splicing of over 90% of human pre-mRNAs, begins with the recruitment of U1 snRNPs (small nuclear ribonucleoprotein particles) to the pre-mRNA 5’ exon/intron junction via base pairing of the U1 snRNA with the splice site. U2 snRNPs subsequently bind to the pre-mRNA branchpoint sequence (BPS) near the 3’ intron boundary, also in part via base-pairing interactions. Further remodeling of the spliceosome results in the recruitment of additional snRNPs, including U6 snRNPs that will replace U1 snRNPs at 5’ pre-mRNA splice sites. Base pairing of U6 with U2 snRNAs juxtaposes the 5’ splice site and the BPS, the reactants of the first transesterification reaction. Thus, recognition and removal of introns and subsequent exon ligation depend in part on the dynamic base pairing of snRNAs with pre-mRNAs and with each other.

Given the critical importance of pre-mRNA splicing to the regulation of gene expression and proteome diversity, it follows that mutations in RNA-processing proteins that may influence pre-mRNA splicing cause human disease (Cooper et al., 2009; Licatalosi and Darnell, 2006). Indeed, dominant mutations in multiple ubiquitously expressed protein components of the U4/U5/U6 tri-snRNP cause retinitis pigmentosa (Mordes et al., 2006). Mutations in the \( \text{SMN} \) (survival of motor neuron 1) gene, which encodes a protein essential for U snRNP biogenesis, cause motor neuron degeneration in patients with spinal muscular atrophy (SMA) (Lefebvre et al., 1995). Although \( \text{SMN} \) is ubiquitously expressed, alterations in the levels of individual snRNAs and numerous aberrant transcripts were observed in a tissue-specific fashion in \( \text{SMN} \)-deficient mice (Zhang et al., 2008). Mutations in genes encoding the ubiquitously expressed DNA/RNA-binding proteins, TDP-43 and FUS/TLS, are associated with some cases of familial and sporadic amyotrophic lateral sclerosis and frontotemporal dementia (Lagier-Tourenne et al., 2010; Lemmens et al., 2010). Recent studies demonstrated that decreased expression or altered subcellular localization of TDP-43 resulted in reduced expression and altered splicing of multiple mRNAs (Polymenidou et al., 2011; Tollervey et al., 2011). These findings strongly implicate alterations in RNA processing as a key event in several neurodegenerative disorders. However, given the multiple functions of these proteins, the pathogenic basis of these diseases remains unclear.

Recently, mutations in the gene encoding U4atac snRNA, a component of the minor spliceosome that splices a restricted (U12-dependent) class of introns found in less than 1% of human genes, have been linked to the developmental disorder microcephalic osteodysplastic primordial dwarfism (Edery et al., 2011; He et al., 2011). However, to date, mutations in the major spliceosomal snRNA genes have not been associated with disease, perhaps in part due to their ubiquitous expression and essential function. Furthermore, unlike the \( \text{U4atac} \) gene, the snRNAs of the major spliceosome are encoded by multiple genes and pseudogenes in metazoans (Marz et al., 2008), suggesting that these genes are highly redundant. Although differing in organization (e.g., U1 and U2 genes exist in large chromosomal
clusters in the human genome, whereas other snRNA genes are not clustered; Manser and Gesteland, 1982; Van Arsdell and Weiner, 1984; Westin et al., 1984). Sequence analysis of snRNA genes suggests that they have apparently undergone concerted evolution, i.e., members of gene families are identical or nearly so within a species (Marz et al., 2008; Pavelitz et al., 1995). However, the effect of polymorphisms in individual members of these repetitive gene families on pre-mRNA splicing and the extent to which the expression of single genes is independently regulated are largely unknown.

Here, we report that a 5 nucleotide (nt) deletion in one member of a cluster of mouse U2 snRNA genes causes neurodegeneration and alternative splicing defects, including the retention of small introns. Our study provides definitive evidence for the causative role of splicing dysfunction in neurodegeneration and a model to dissect the role of major spliceosomal snRNAs on the regulation of mammalian pre-mRNA splicing.

RESULTS

Progressive Neurodegeneration in NMF291 Mutant Mice

The NMF (Neuroscience Mutagenesis Facility) 291 mutation was identified in a chemical mutagenesis screen for recessive mutations that result in neurological phenotypes (Bult et al., 2004). Mice homozygous for this mutation developed mild tremors by 8 weeks of age, which progressed to overt truncal ataxia by 12 weeks (see Movie S1 available online). At 4 weeks of age, the brains of mutant mice appeared grossly normal (Figures S1A–S1D). However, histological analysis revealed granule cells with pyknotic nuclei in the mutant cerebellum beginning at 4 weeks of age (data not shown). Neuron loss was progressive, and by 4 months of age, most granule cells had degenerated (Figures 1A–1F). However, other cerebellar neurons, including Purkinje cells, did not degenerate, even in aged mice (data not shown). Although neuron death was most severe in the cerebellum, later-onset degeneration of granule cells in the dentate gyrus region of the hippocampus was also observed (Figures S1E–S1H).

To determine the nature of neuron death, immunostaining with activated caspase-3 antibodies was performed on cerebellar sections from 6-week-old mice. Many immunopositive granule cells were observed in the mutant, but not the wild-type (WT) cerebellum, suggesting that mutant neurons undergo apoptosis (Figures 1G and 1H). Granule cell apoptosis was confirmed by TUNEL (TdT-mediated dUTP nick end labeling) analysis (Figures 1I and 1J).

The NMF291 Mutation Deletes 5 nt in the Rnu2-8 U2 snRNA

The NMF291 mutation was initially localized to distal Chromosome 11 by a genome scan analysis of F2 mice using polymorphic microsatellite markers. Additional recombination mapping narrowed the mutation interval to a 0.52 cM (0.34 Mb) region between D11Mit200 and D11Mit199 containing eight protein-coding genes (Figures S2A, 2B, and S2A). No coding sequence polymorphisms between mutant and WT DNA were found in these genes, nor did we observe differences in the expression of the cerebellar transcripts of these genes between genotypes (data not shown).

In addition to the protein-coding genes, a cluster of five U2 snRNA (Rnu2-6 to Rnu2-10) genes also resides in the NMF291 critical interval (Figure 2B). The RNAs encoded by these genes are identical, except for a single nucleotide polymorphism in Rnu2-6 (Figure S2B). Sequencing of mutant genomic DNA revealed a 5 bp deletion between nt 30 and 34 (30AGUGU34) in a highly conserved region of the Rnu2-8 transcription unit (Figures 2C and 2D). This deletion removes the first 2 nt of the U2 consensus branch site recognition sequence (BSRS)

and the 3 nt linker region (30AGU33) between the BSRS and U2/U6 helix IA (Figures 2D and 2E) (Wahl et al., 2009). The deletion was not observed in genomic DNA from several other inbred stains, including C57BL6/J and 129S4/SvJae, from which the F1 ES cells used for mutagenesis were derived (data not shown).

**Figure 3. The Expression of Rnu2-8 Is Temporally and Spatially Regulated**

(A and B) Total RNA from WT and NMF291+/− (−/−) P30 cerebella was separated by denaturing acrylamide gels for shorter (A) or longer (B) periods and subsequently analyzed by northern blot analysis using an U2-specific oligonucleotide probe. For loading controls, the gel was stained with ethidium bromide (A, bottom), or the membrane was rehybridized with a probe for 5S rRNA (B).

(C) RPA using increasing amounts of cerebellar RNA (0.2–1 μg) from P30 WT and NMF291+/− mice. For loading controls, RPA was also performed using a β-actin RNA probe.

(D) RPA analysis of U2 snRNAs in various tissues taken from P30 WT and NMF291+/− mice.

(E) RPA analysis of U2 snRNAs in WT, NMF291+/− (+/−), and NMF291+/− cerebella at different postnatal (P) ages (days after birth). Cere., cerebellum; S.C., spinal cord. See also Figure S3.

**Rnu2-8 Is Spatially and Temporally Regulated**

To confirm that the U2 gene disrupted by the NMF291 deletion is indeed expressed, we performed northern blot analysis and RNase protection assays (RPAs) using cerebellar RNA isolated from P30 WT and mutant mice. Total U2 snRNA levels were similar between the WT and the NMF291+/− cerebellum (Figure 3A), and both WT and the deletion-containing Rnu2-8 RNAs were detected in the mutant cerebellum (Figures 3B and 3C), with the mutant transcript found at 78.9% ± 6.3% (n = 6) of the level of the WT U2 snRNA (or ~45% of total U2 levels). Similar analysis of highly pure granule cell cultures demonstrated that both WT and mutant U2 RNAs were expressed within the same cell type (data not shown). Finally, immunoprecipitation experiments using Y12 antibody, which precipitates U snRNPs (Lerner et al., 1981), demonstrated that the mutant U2 snRNAs were assembled into mutant cerebellar U2 snRNPs (Figures S3A and S3B), consistent with previous reports that the free snRNA pool is relatively very small and unstable (Sauterer et al., 1988).

Mammalian U2 snRNAs, like other U snRNAs, are believed to be ubiquitously and highly expressed (Egloff et al., 2008; Hernandez, 2001). However, neurodegeneration in NMF291+/− mice was very distinct, with profound neuron loss occurring within the cerebellum beginning at P30. To determine if expression of mutant Rnu2-8 correlates with the specificity of pathological changes, we performed RPA and northern blot assays using neuronal and non-neuronal tissues from the P30 WT and

homozygous mutant mice (Figures 3D and S3C). Surprisingly, mutant Rnu2-8 was differentially expressed between tissues, with highest levels observed in the cerebellum. Furthermore, mutant Rnu2-8 expression was also temporally regulated in the postnatal cerebellum. Mutant U2 RNAs comprised 20%–25% of the total U2 RNA levels in the P10 and P20 NMF291+/− cerebellum but rose to ~45% of the total level at P30 (Figures 3E, S3D, and S3E). This increase was maintained at P40 but dropped slightly at P60, likely due to neuron loss in the mutant cerebellum. This temporal regulation of expression was also observed in heterozygous mice, where amounts of mutant U2 RNA were approximately half of that observed in homozygous mice (Figures 3E and S3E). Together, these data suggest that mammalian U2 snRNAs display previously unsuspected temporal and spatial variation with the expression of mutant Rnu2-8 correlating with the onset and specificity of neurodegeneration in the NMF291+/− mouse.

Mutant Rnu2-8 Induces Neurodegeneration in a Dosage-Dependent Manner

Although mice homozygous for the NMF291 mutation were originally ascertained in our screen, the site of the Rnu2-8 deletion, the multicopy nature of the U2 genes, and the expression of WT U2 snRNAs in the mutant cerebellum suggested that this mutation might act in a gene dosage-dependent fashion. To investigate this possibility, we performed histological analysis of the cerebellum of NMF291+/− mice. Apoptotic granule cells were observed in the cerebellum of 1-month-old and older NMF291+/− mice, but the number of dying neurons was considerably reduced compared to that observed in homozygous NMF291 mice (data not shown). Differences in the overall size of the NMF291+/− cerebellum were not obvious until mice were close to 2 years of age, when mild tremors were apparent, and histological analysis revealed that many granule cells had degenerated (Figures 4A–4F).

To further test the mechanism of the Rnu2-8 mutation, we generated mice transgenic for a 1.5 kb genomic DNA fragment containing the mutant Rnu2-8 transcriptional unit and the basal regulatory elements necessary for U2 transcription and processing (Figure 4G) (Egloff et al., 2008; Hernandez, 2001). Mice from one transgenic line (Tg-MuU2) expressed mutant Rnu2-8 in the cerebellum, and expression was temporally and spatially regulated similar to that observed in NMF291+/− mice (Figures 4H–4J and S4A). Like NMF291+/− mice, hemizygous mice from this line developed pronounced ataxia by 12 weeks of age (data not shown). Histological analysis revealed dying granule cells in the cerebellum of 1-month-old transgenic mice, and by 3 months of age, most granule cells had died, similar to the

time course of neuron death in NMF291−/− mice (Figures 4K and 4L; data not shown). As observed in NMF291−/− mice, neuron loss in the dentate gyrus was observed in 3-month-old transgenic mice (Figures S4B and S4C).

If the severity of neurodegeneration is indeed dependent on the ratio of mutant to WT snRNAs, then the complementary experiment in which an increase in expression of WT U2 RNA on the NMF291−/− background should lead to attenuation of pathology. To test this hypothesis, we generated a transgenic mouse line carrying a BAC (bacterial artificial chromosome) containing Rnu2-8 and two other U2 genes (Rnu2-9 and -10; Figure 5A). This line was crossed to NMF291 mice to generate NMF291−/− mice carrying the BAC transgene. The percentage of mutant/total U2 snRNA was reduced in the cerebellum of Tg-268K4; NMF291−/− and Tg-268K4; NMF291−/− mice relative to that observed in the cerebellum of age-matched NMF291−/− and NMF291−/− mice (Figures 5B, S3A, and S5B). Neurodegeneration was also decreased in the cerebellum of 3-month-old Tg-268K4; NMF291−/− mice relative to that of age-matched NMF291−/− mice (Figures 5C–5F). Surprisingly, when mutant U2 RNAs represented ~17% of total U2 levels, little granule cell loss was observed in aged Tg-268K4; NMF291−/− mice (Figures S5C–S5F). When the percentage of mutant/total U2 RNA increased to ~25% as observed in the NMF291−/− cerebellum, neurodegeneration was slowly progressive (Figures 4A–4F). However, when this percentage reached ~45% (as in the P30 NMF291−/− and Tg-MuU2 cerebellum), rapid granule neuron loss was observed (Figures 1C and 4L). Taken together, our data demonstrate that the expression of the mutant Rnu2-8 gene is sufficient to induce granule cell death even in the presence of WT U2 expression, and the extent of neuron loss is dependent on the expression level of the mutant U2 snRNAs relative to that of the WT U2 snRNA.

Expression of the Mutant U2 snRNA Decreases Splicing Efficiency

The central role of U2 snRNA in pre-mRNA splicing suggested that abnormalities in this process underlie neurodegeneration in NMF291−/− mice. To study the impact of the mutant Rnu2-8 on pre-mRNA splicing, we employed a previously reported splicing reporter construct, TN24 (ISS+), which encodes both β-galactosidase and luciferase separated by an exon-intron-exon cassette (Kollmus et al., 1996; Nasim et al., 2002). Although β-galactosidase is constitutively expressed from this plasmid, luciferase is only expressed when accurate splicing occurs between the adenovirus 5′ exon and the alternatively spliced SK exon of human Tpm3 (see diagram in Figure 6C).

HEK293T cells were transfected with ISS+ alone, or cotransfected with the reporter and a 1.5 kb genomic DNA fragment containing the WT or the mutant (Δ5nt) U2 transcription unit (Figures 6A–6C). As controls, cells were cotransfected with the reporter and a plasmid encoding the RNA-binding protein hnRNPG, which has been shown to silence splicing of this plasmid, luciferase is only expressed when accurate splicing occurs between the exon-intron-exon cassette via binding of the 25 bp intronic-splicing silencer (ISS) (Nasim et al., 2002). Transfection of WT Rnu2-8 did not have a significant effect on reporter splicing as determined by the ratio of luciferase/β-galactosidase activity or by RT-PCR (Figure 6C). However, transfection of mutant Rnu2-8 led to a significant decrease (28%; p < 0.01) in the splicing efficiency of the reporter compared to that of cells transfected with reporter alone.

Similar experiments were performed using the same reporter lacking the 25 bp ISS (ISS−) (Nasim et al., 2002) (Figure 6D). In agreement with the role of the ISS sequence in splicing silencing, we observed a 4- to 5-fold increase in splicing of this reporter over that of the reporter containing the ISS sequence. As previously shown (Nasim et al., 2002), the inhibitory effect of hnRNPG expression on ISS− reporter splicing was greatly reduced (Figure 6D). As observed for the ISS+ reporter, splicing of the ISS− reporter was not changed by expression of the WT U2. However, in contrast to the attenuation of ISS+ reporter splicing...
Figure 6. Mutant Rnu2-8 Selectively Decreases Splicing Efficiency of Introns

(B) RPA analysis of RNA from mock-transfected HEK293T cells or cells transfected with WT or ∆U2 plasmids.

(C and D) HEK293T cells were transfected with the ISS+ splicing reporter (C) or the ISS−/C0 splicing reporter (D), or cotransfected with WT or ∆U2 constructs as indicated. The splicing of pBPLUGA parental vector is shown in (C) as a control, and the splicing of the ISS+ reporter is shown in (D) as a reference. The splicing efficiency of the reporters was measured by luciferase/β-Gal (β-galactosidase) activity (top panels in C and D) and confirmed by RT-PCR (bottom panels). Values represent mean ± SEM, n = 3; *p < 0.01; one-way ANOVA. Asterisk (*) and arrows in reporter diagrams denote stop codons and RT-PCR primers, respectively.

(F) RT-PCR was performed on WT (+/+ ) and NMF291−/− (-/-) cerebellar cDNA at indicated ages.

(G and H) HEK293T cells were transfected with L1CAM exon 27-intron 27-exon 28 (G) and exon 28-intron 28-exon 29 (H) splicing reporters with or without WT or ∆U2 constructs as indicated. Splicing of these reporters was analyzed as described above in (C) and (D). As references, the spliced RT-PCR products of exon 27-intron 27-exon 28 reporter and the unspliced PCR product amplified from the exon 28-intron 28-exon 29 reporter plasmid (DNA) are also shown in (H). Values represent mean ± SEM, n = 3; *p < 0.01; one-way ANOVA. Asterisks (*) in reporter diagrams denote stop codons.
by expression of the mutant U2 construct, expression of the mutant U2 did not significantly affect splicing of the ISS—reporter. These results suggest that alterations in splicing efficiency mediated by the expression of the mutant U2 snRNA may be dependent on the presence of splicing regulatory sequences.

The presence of intronic or exonic splicing regulatory sequences often accompanies alternative splicing of pre-mRNA (Black, 2003); thus, we initially analyzed several alternative-splicing events that were previously reported to occur in the human cerebellum (Wang et al., 2008). Of the 20 alternative splicing events, including 1 in the neural cell adhesion molecule L1 (L1CAM), 4 displayed obvious changes in relative isoform expression between the WT and NMF291−/− cerebellum (data not shown). PCR amplification of the distal exons of the L1CAM transcript from WT cerebellar RNA generated two isoforms: the major form containing exons 27-28-29, and a minor isoform that retains the 95 bp intron located between exons 27 and 28 (Figures 6E and 6F). Coincident with the decrease of the fully spliced isoform, the abundance of the intron 27-containing isoform was increased in mutant cerebellar RNA. Interestingly, these alterations in splicing were most dramatic in the P30 and P40 cerebellum, demonstrating that the change in the ratio of splicing variants was temporally regulated in a manner coincident with expression of the mutant U2 snRNA.

To directly evaluate the effects of the mutant U2 on splicing of intron 27, we generated L1CAM splicing reporters. A cassette containing exon 27, the alternatively spliced intron 27, and exon 28, or a cassette with exon 28, the constitutively spliced intron 28, and exon 29 were cloned into the pBPLUGA plasmid (Figures 6G and 6H). These plasmids were cotransfected into HEK293T cells with the WT or mutant Rnu2-8 plasmid. Transfection of the intron 27-containing reporter resulted in both spliced and unspliced transcripts as evidenced by RT-PCR (Figure 6G). In contrast only spliced transcripts were observed in cells transfected with the intron 28-containing reporter, although not as efficiently as cotransfection of the reporter with Δ5 Rnu2-8, suggesting that the deletion of 2 nt of the BSRS may also contribute to the Δ5 effect on splicing (Figure 6G). Cotransfection of the Δ3 plasmid with the intron 28-containing reporter again led to an increase rather than decrease of splicing, as did expression of the Δ6 and Δ9 plasmids (Figure 6H). Our data suggest that expression of a U2 snRNA with either the NMF291-associated 5 nt deletion or lacking the linker sequence between the BSRS and the U2/U6 helix IA disrupts select intron splicing.

**Abnormal Alternative Splicing in the NMF291 Mutant Cerebellum**

To analyze alternative splicing in the NMF291 mutant cerebellum, exon expression was examined by Affymetrix mouse exon 1.0 ST microarrays. Microarrays were hybridized with RNA from three WT and three NMF291−/− cerebella isolated at P30, a time when the mutant U2 RNA is expressed at peak levels, but few neurons have degenerated (Figures S1A–S1D, 3E, and S3E). A total of 123 genes were differentially expressed between the WT and mutant cerebellum, as demonstrated by analysis of signal across all probe clusters for a gene (fold change ≥ 1.5; p < 0.05) (Table S1A). Differential expression of most (78%) of these genes was relatively low (1.5- to 2-fold), suggesting that overall gene expression was not dramatically altered in the P30 mutant cerebellum.

Paired analysis of the exon splicing index (SI), which was calculated by normalizing exon expression to gene level expression (Clark et al., 2007; de la Grange et al., 2010), revealed that the expression of 206 exons in 178 genes was differentially expressed between the WT and mutant cerebellum (SI fold change ≥ 1.5; p < 0.05) (Table S1B). These exons were compared to the comprehensive list of known human and mouse splice variants in the FAST DB database (de la Grange et al., 2007), and 146 (71%) events, representing all major types of alternative splicing patterns, were previously annotated as alternatively spliced.
(Table S1B; Figure 7A). To validate our exon array results, RT-PCR was performed using cerebellar cDNA from four independent mice of each genotype. Of these events, 92% (12 of 13) were validated as differentially spliced between the WT and mutant cerebellum (Figure S6A; data not shown).

Interestingly, 14% of the differentially spliced events detected by exon array analysis were annotated as alternatively spliced introns, although introns normally represent a very minor (1%–3%) class of alternative splicing events (Chacko and Rangamathan, 2009; de la Grange et al., 2010; Wang et al., 2008). To examine this more closely and to expand our exon array results, we performed RNA-Seq analysis. Libraries were prepared from cerebellar mRNA from three P30 mutant and two P30 WT mice and sequenced. The resulting reads were aligned to the mouse genome reference sequence via SpliceMap (http://www.stanford.edu/group/wonglab/SpliceMap/), an algorithm that maps exon-exon junctions without relying on previous exon annotations for recovering the splicing junctions (Au et al., 2010). A total of 53.48 ± 6.35 × 10^9 reads per sample were uniquely mapped to the mouse genome, and 61.23% ± 1.18%, 20.80% ± 1.54%, and 6.20% ± 0.19% of these reads uniquely mapped to exons, introns, and splice junctions, respectively (Table S1C).

To identify alternative splicing pattern changes between the WT and NMF291+/− cerebellum, splicing junction reads were extracted and normalized for isoform expression to generate the Relative Junction Index (RJI) (Figure S6). Comparison of the RJI between the two genotypes identified 1,636 junctions that were differentially expressed (RJI ratio ≥ 2.0; p < 0.05; Table S1D). In addition, 52 and 1,137 junction reads that were present only in the WT and mutant data sets, respectively, indicated that many splicing variants in the mutant cerebellum were not present, or present at a very low levels, in the WT cerebellum (Table S1E). As described above, RT-PCR using WT and mutant cerebellar cDNA was performed to test differential splicing of junctions. A total of 20 of 20 junctions that were originally identified in both genotypes and 20 of 21 (95%) of the junctions identified only in 1 genotype were validated (Figures S6B and S6C; data not shown).

To examine global abnormalities in splicing of introns in the mutant cerebellum, we calculated the Relative Intron retention Index (RII) from our WT and mutant RNA-Seq data sets (Figure S6). Comparison of WT and mutant RII indicated that 3,978 introns were retained at higher levels in the mutant cerebellum (RII ratio ≥ 2; p < 0.05, Figure 7B; Table S1F), including intron 27 of L1CAM (RII ratio = 3.55; p = 0.0012). In contrast, we identified only 362 introns that were retained at higher levels in the WT cerebellum (RII ratio ≥ 2; p < 0.05). To check the validity of our analysis, we performed RT-PCR on 23 introns that were present at higher levels in the mutant transcriptome by RNA-Seq, and all were validated (Figures S6D and S6E; data not shown). Furthermore, 19 of 23 (82.61%) of these introns, like intron 27 of L1CAM, and 5 of 7 RT-PCR-validated introns identified by exon array, were also present in WT cerebellum as a minor isoform (Figures S6A and S6D). These results indicate that these introns represent alternative splicing events and are likely to be suboptimal pre-mRNA substrates even in presence of the WT spliceosome. Previous studies have shown that small introns are prone to being retained in human and mouse transcripts in physiological conditions (Sakabe and de Souza, 2007). These prompted us to check the size distribution of the intron retention events identified by RNA-Seq. Indeed, 30.62% of the retained introns in the mutant cerebellum were less than 100 bp, which largely differs from the size distribution of introns in the mouse genome (RefSeq: 5.31% < 100 bp) or those significantly retained in the WT cerebellum (3.31% < 100 bp) (Figure 7C). As expected, differences in splicing of small introns removed by the U12-dependent minor spliceosome were not observed in the mutant cerebellum (Figure S6F). Thus, both exon array and RNA-Seq analysis demonstrated that a group of alternative splicing events, including the splicing of small introns, was altered in the NMF291+/− cerebellum.

To check the overlap of our exon array and RNA-Seq analysis, we compared intron retention events (Table S1H). Of these events, 96.4% (27 of 28) detected by exon array displayed differences in the same direction in RNA-Seq data, although only 46.4% (13 of 28) passed our stringent threshold set for RNA-Seq analysis. Although differential events in other splicing event categories ascertained by both analyses were clearly validated by RT-PCR, little overlap was observed in the data sets, likely due to the different experimental and analysis parameters used in the two methods (see Extended Experimental Procedures).

The role of U2 snRNA as a basal component of the spliceosome would predict that splicing of transcripts encoding proteins across many functional classes would be disrupted in the mutant cerebellum. Indeed, splicing alterations between the WT and mutant cerebellum occur in genes with many predicted cellular roles (Tables S1B and S1D–S1F). However, Gene Ontology (GO) analysis of the differentially expressed junctions and spliced introns detected by RNA-Seq and exon array analysis revealed that genes annotated to GO terms of nucleoplasm (GO:0005654) were significantly enriched, as were those annotated to ribonucleotide binding (GO:0032553) (Table S1G). Interestingly, after these two functional clusters, the most significantly enriched genes in the differentially spliced intron data set were annotated to mRNA processing (GO:0006397), including those annotated to the spliceosomal complex (GO:0005681) (Figure 7D; Table S1G). Differentially expressed exons and genes also showed significant enrichment for mRNA processing, although at higher p values.

**DISCUSSION**

We demonstrate that a mutation in one of the multicopy mouse U2 snRNA genes causes defects in pre-mRNA splicing, leading to neurodegeneration. U2 snRNAs play an essential role in formation of the catalytically active spliceosome by base pairing with both the intron branch point and the U6 snRNA (Wahl et al., 2009). Expression of the mutant U2 snRNA alters pre-mRNA splicing at selective splice sites that are often associated with alternative splicing, demonstrating that U-snRNA dysfunction, like downregulation of core spliceosomal proteins, can influence splice site choice (Corioni et al., 2011; Park et al., 2004; Saltzman et al., 2011; Shaw et al., 2007).

One of the main pathological features of the NMF291+/− cerebellum is the increased retention of small introns, which likely
Figure 7. Global Splicing Abnormalities in the NMF291−/− Cerebellum

(A) Types of alternative splicing events identified by exon array analysis as differentially spliced between the WT and the NMF291−/− cerebellum. A3SS, alternative 3′ splice site; A5SS, alternative 5′ splice site; AFE, alternative first exon; ALE, alternative last exon; MXE, mutually exclusive exon; T3UTR, truncated 3′ UTR.

(B) The log of the mutant/WT IRI generated by RNA-Seq analysis plotted against the log of the intron length (bp).

(C) Significantly retained introns in the cerebellum of NMF291−/− or WT mice, or RefSeq introns were grouped by length and plotted as a percentage of the total introns.

(D) GO analysis of genes annotated to the pre-mRNA splicing GO term were significantly enriched in the differentially spliced exons (Diff. junctions) and introns (Diff. introns) identified by RNA-Seq, and differentially spliced exons (Diff. exons) and differentially expressed genes (Diff. genes) identified by exon array. Percentage is the number of genes (the numerator in parentheses) annotated to the GO term divided by the total number of inputted genes (the denominator in parentheses). Fold enrichment is the magnitude of enrichment of input genes relative to all mouse genes annotated to pre-mRNA splicing. The p value indicates the significance of gene-term enrichment with a modified Fisher’s exact test.

(E) The working model for our findings. The splicing status and biological consequences of expression of WT (blue) and NMF291 mutant (red) U2 snRNAs in WT and NMF291−/− neurons are shown. Our in vivo and in vitro data suggest that expression of mutant U2 snRNA disrupts splicing at many suboptimal or weaker splice sites, including some of those used in alternative splicing. These changes in alternative splicing may be further amplified by altered splicing of RNA-processing factors caused directly by mutant U2 snRNAs or by autoregulation.

See also Figure S6 and Tables S1A–S1H.
represents unique spliceosomal substrates. Unlike splicing of large introns, which is thought to first occur by pairing of splice sites across the exon (“exon definition”), splicing of short introns likely occurs by pairing of 5’ and 3’ splice sites across the intron (“intron definition”) (Berget, 1995). Furthermore, even under normal physiological conditions, many of the highly retained introns in the mutant cerebellum are not fully spliced, consistent with the observation that weak splicing sites often flank small introns (Lim and Burge, 2001; Sakabe and de Souza, 2007). Given the disruption of short intron splicing and other alternative splicing events, it is plausible that mutant U2 snRNPs are fully functional on optimal, but not suboptimal, substrates (Figure 7E).

Interestingly, we found that mRNA-processing genes were significantly enriched among the alternative splicing events differentially expressed between the WT and mutant cerebellum, suggesting that neurons may utilize alternative splicing to regulate the function of proteins involved in RNA splicing and processing in an effort to restore splicing homeostasis. Indeed, studies have shown that a number of splicing regulators autoregulate their expression and activity via transcriptional feedback loops and alternative splicing (Ni et al., 2007; Saltzman et al., 2011; Wollerton et al., 2004). However, rather than reestablishing homeostasis, these splicing alterations could in fact act to amplify the amount of abnormal splicing and ultimately prove deleterious. It will be intriguing to see whether the expression level and/or alternative splicing status of these mRNA-processing genes is also affected in SMA patients or ALS/FTD patients with mutations in TDP-43 or FUS/TLS.

The ultimate cause of neuron death in the mutant cerebellum is unclear. Cell death could be caused by the generation of proteins with altered function or by the production of RNAs containing abnormal sequences, which could themselves be toxic as previously reported for trinucleotide repeat expansion diseases (Li et al., 2008). Retained introns may also contribute to neuron death by depleting splicing regulators and/or other RNA binding proteins. In addition, many of these introns likely harbor premature translation termination codons (PTCs) that would be predicted to trigger the nonsense-mediated mRNA-decay (NMD) pathway. In addition to its role in degradation of abnormal transcripts, NMD also regulates many natural PTC-containing transcripts, including those involved in synaptic physiology and cellular stress (Gardner, 2010; Giorgi et al., 2007). Enhanced and/or prolonged NMD activation could overwhelm the NMD pathway, causing dysregulation of normal NMD targets that might be essential for cell survival, or itself cause cellular stress.

Finally, our data demonstrate the potential for disease-causing mutations in multicopy genes. Although a single U2 gene is present in yeast, multiple copies of these genes exist in higher organisms, each producing identical or nearly identical products. Indeed, the region on human Chromosome 17p21 (homologous to the Rnu2-6 to Rnu2-10-containing region on mouse Chromosome 11) also contains a cluster of stably inherited U2 genes that vary in copy number from 5 to 25 (Van Arsdell and Weiner, 1984; Westin et al., 1984). In addition to our findings of temporal and spatial regulation of a mouse U2 gene, developmental regulation of other snRNA genes, including U2 snRNA genes, has been reported (Forbes et al., 1984; Lund et al., 1985; Sierra-Montes et al., 2005; Stefanovic et al., 1991). Furthermore, the developmental arrest associated with homozygosity for a mutation in 1 of 12 C. elegans U1 genes raises the possibility of differences in expression and/or function between C. elegans U1 genes (Zahler et al., 2004). Whether individual human U2s (or other multicopy genes) are differentially expressed during development, in different cell types, or even as a result of pathogenic processes is unknown. However, the potential for discrete regulation of individual members of multi-gene families, combined with their potential for copy number variation, increases the prospect of uncovering disease-causing mutations in repetitive genes.

**EXPERIMENTAL PROCEDURES**

**Mice**

The NMF291 mutant strain was derived from EMS-treated ES cells and a two-gene mating scheme, as described previously (Munroe and Schimenti, 2009). Genetic mapping of the NMF291 mutation was performed using an intersubspecific intercross (B6; 129 NMF291 × CAST/Co). The Jackson Laboratory Animal Care and Use Committee approved all animal protocols.

**Histology Analysis**

Hematoxylin and eosin staining was performed on Bouin’s fixed tissue. Cleaved Caspase-3 (Cell Signaling) immunostaining and TUNEL assays (Roche) were performed as described previously (Zhao et al., 2005). At least three mice of each genotype were used for all histological analyses.

**RPA, Northern Blot Assay, and RT-PCR Assay**

Total RNA was extracted by TRIzol (Invitrogen) and treated with DNase I (Ambion). RPA analysis was performed as suggested by the manufacturer’s instructions (Ambion). For northern blots, total RNA was separated by 10% denaturing polyacrylamide gel, and the membrane was hybridized with end-labeled DNA oligo probes. RT-PCR was performed on random-primed cDNA (Invitrogen). Primers used for RT-PCR are described in Table S2. Density of bands in scanned X-ray films was determined by ImageQuant 5.2 software (Amersham).

**Constructs, Cell Culture, Transfection, and Luciferase Assays**

The mutant Rnu2-8 DNA fragment used for generating transgenic mice and the corresponding WT DNA fragment were cloned into pCR2.1-TOPO for expression of WT and mutant U2 snRNA in cultured cells. The Δ3, Δ6, and Δ6-U2 snRNA and ISS - expression constructs were generated by site-directed mutagenesis (Stratagene). Primers used for construct generation are described in Table S2B. HEK293T cells were used for transient transfection (Lipofectamine 2000; Invitrogen). Luciferase and β-galactosidase activities (Promega) were measured in a multilabel counter 48 hr after transfection. Statistical significance was determined by ANOVA analysis (SPSS).

**Exon Array, RNA-Seq, and Functional GO Analysis**

Data treatment of Mouse Exon 1.0 ST Arrays (Affymetrix) was done by the EASA analysis and the interface visualization system (GenoSplice Technology, http://www.genosplice.com), which is based on the FAST DB annotations (de la Grange et al., 2007). Probe selection and statistical analysis were performed as previously described (Clark et al., 2007; de la Grange et al., 2010). The GEO (Gene Expression Omnibus) accession number for our exon array data is GSE33069. For RNA-Seq, mRNA purification and DNA library preparation were performed according to the manufacturer’s protocol (Illumina). The library was sequenced on Illumina GAIIx using paired-end read strategy. For de novo identification of junctions, the reads were inputted to SpliceMap 3.3.6 (Au et al., 2010) and aligned to the mouse reference genome. A workflow chart of our RNA-Seq analysis is shown in Figure S6G. RefSeq intron length information was extracted from UCSC. The GO analysis was conducted by using DAVID bioinformatics resources 6.7 (Huang da et al., 2009). Primers
used for exon array and RNA-Seq validation experiments are described in Table S2C.

ACCESSION NUMBERS

Our exon array data have been deposited into the GEO. The GEO accession number is GSE33069. The databank accession numbers for the Rnu2-6, Rnu2-7, Rnu2-8, Rnu2-9, and Rnu2-10 sequences reported in this paper are JN863957, JN863958, JN863956, JN863959, and JN863960, respectively.

SUPPLEMENTAL INFORMATION

Supplemental Information includes Extended Experimental Procedures, six figures, two tables, and one movie and can be found with this article online at doi:10.1016/j.cell.2011.11.057.

ACKNOWLEDGMENTS

We thank The Jackson Laboratory sequencing, gene expression, histology, microinjection, and multimedia services for their assistance. We also thank W.H. Wong for discussions on RNA-Seq analysis, J. Blake and C. Bult for discussion on GO analysis, L. Beverly-Stagg and J. Cook for mouse husbandry assistance, P. de la Grange for exon array analysis, J. Hammer and L. Zhao for graphics assistance, J. McCarthy and M. Nasm for plasmids, and R. Burgess, G. Cox, and M. Hibbs for comments on the manuscript.
